INTRODUCTION

BEACON denotes a set of programs organized to form a computing tool to study defense of the continental United States against strategic nuclear attack. The work has been predominately supported by the USAF, Headquarters Systems Command under contract AF 18(600)-2793. The purpose is not to evaluate current force structures (although this is not an unreasonable application), but rather to obtain a feel for the possibilities of newer technological concepts. Wild fresh ideas may form the other end of the application spectrum, though it is usually advisable to trim them down first by traditional study phases.

Thus, BEACON has not been designed toward the study of a particular weapon system or even type of systems, but (in intent at least) toward embracing the whole set of potentially interesting interacting systems of the near future. Since it is difficult for a small set of people to be good visionaries over such a vast realm, the method of procedure has been to concentrate on fundamental logical or physical processes of attack and defense on a global scale and to keep the structure modular, replaceable, and open-ended. It has not been easy. A distinction must be made between the general procedure that may be termed BEACON and any particular representation of it that may exist at a particular time such as BEACON I or II or III, etc. It is inevitable that representations be incomplete or unsuitable for the "next!"

application. Success is often a combination of existence and adaptability. In this light the representation included here can only be regarded as a transitory example of the general procedure.

BEACON is not a model, at least not according to the usual thoughts that the word model evokes. The germanic concept that distinguishes a model is the occurrence of a central or main program that controls the processing flow according to some built-in logic which imitates or captures the essence of some real life activity. A key word lies in built-in. The fact that most models permit selective control or parameter variation through inputs at run time, cannot destroy the essential feature of a definable pre-understood logical path. By contrast BEACON substitutes for the central program a monitor which controls during execution other semantic component programs for the user in the way the user specifies. The entity takes the form of a computation by request, in the order of request, and to the extent requested. It is not farfetched to say that BEACON passes on to the user the joy (and the task) of "writing" his own main program at each execution. The method is simple and flexible enough to suit most user type needs without the elaborate procedure a programmer uses of actually writing and compiling a central program. The user pays an initial price in understanding and organizing his problem, but gains a degree of freedom and participation. Although the subject matter obviously prohibits classifying BEACON as a general purpose software, within its scope this is its spirit.

SECTION I

Since BEACON does not have a prescribed logic, one cannot draw a very informative flow diagram. It seems best in this circumstance to discuss each of the main programs and then to illustrate some ways they may be exercised on defense problems. The function of the monitor BEAM is only to aid in effecting the latter and will be discussed later.

ATLAS

Almost always ATLAS will be the first program a user will wish to perform. The job which is accomplished by ATLAS is to initially set up in core memory what is called a facility record. The information content of the facility record is to be a description of the status of the geographical and physical characteristics of the globally fixed elements essential to the battle. Included in the record will be space for data from some of the other programs. The elements are grouped into sets with each set given a name by which it is referred. What facilities are necessary is solely dependent upon the problem being studied and the programs to be used subsequently. Typically there will be sets to define the targets of the attacker. These may be counterforce, countervalue, or defense sites. US offense bases are often included for this reason. If there is to be an active defense there will be one or more interceptor and/or sensor sets to affect the various battles. Still a third reason

for inclusion of a set may be for damage assessment comparisons. ATLAS decks for the 213 US and 26 Canadian urban areas have been constructed since they are so commonly used for damage assessment.

Thus, the facility record is an open-ended user defined concept.

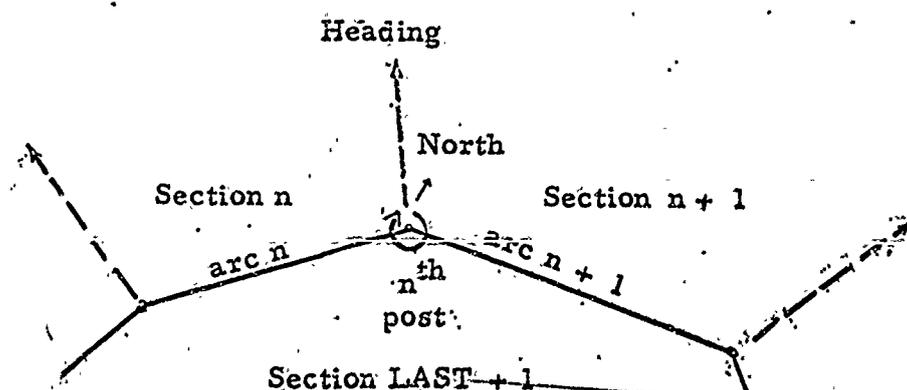

The ATLAS data deck required to supply the detailed information is by far the largest part of the typical input data. The common way of generating such a data deck is to add, delete, or otherwise shuffle a previous deck. With this in mind BEACON is so constructed that it is not necessary for the user to preserve or remember any special order nor to supply counts either of the sites within a set or of the sets themselves. It is incumbent upon the user to remember the names he has used. Another feature which makes it easier to generate an ATLAS deck from cannibalizing existing decks is the personal order and format specification each facility set is permitted. Source data may be presented in a wide variety of forms and more often than not the formats are mixed in any given run. It is then possible to input data for a set of airfields as : name, longitude, latitude, while for urban areas the list may read: population, name, latitude, longitude, area,...

The specific information required about each element depends in part upon the nature of the set. Currently five distinct kinds of

facilities are recognized in BEACON II: sites, blocks, places, barriers, and meshes. Sites are simple homogeneous elements which differ only in location and value, such as may suffice for many types of military bases. The sites of a given set are assumed to have the same physical radius and hardness for targeting and damage assessment purposes. Blocks may be used conveniently when a cluster of point targets are close enough together to be designated as a single squadron or farm and yet far enough apart to require separate targeting, as for example hardened missile silos. Each block is specified as to location, size and unit value. When required each block of a given set will be automatically deployed into a squarish array of the specified number of points around the center of the squadron "headquarters". The hardness and distance between points are set characteristics. Places are used to designate those elements, notably urban areas, which cannot be reasonably regarded as the same size. The individual information in this case includes not only location and value (population), but specific area in square nautical miles. For the three kinds of facilities so far sites, blocks, and places it is optional but recommended that an alphanumeric designation be also stored to identify later printouts.

Barriers and meshes are imaginary facilities; that is they are not targetable nor assessable. Their purpose is to allow the user to introduce a topology into the battle in a form suitable to his problem.

A barrier is formed by simply giving a list of fence post locations, i.e., latitudes and longitudes. In this case the order of the list is meaningful. ATLAS will automatically construct the barrier by connecting great circle arcs between successive posts and will close the ring by connecting the last post back to the first. As the barrier is traversed in ascending order, the arcs are numbered the same as the posts being approached and outward direction is taken to be to the left. Barriers often consist of a dozen or so arcs and may represent such things as probable detection lines, extent of fighter coverage, coastlines, etc. A mesh is an extension of the barrier concept by adding to each post a directional heading. Headings are specified as degrees clockwise from north and normally they are positioned to divide the outward sectors formed by the adjoining arcs. The exterior of the ring is thus subdivided into sections which are numbered the same as the corresponding arc (see illustration). ATLAS constructs great circle arcs so as to be tangent to the headings, and they

form the global extensions of the headings. (A heading of due EAST does not delineate the latitude circle at that point but rather the great circle tangent to the latitude circle.) The interior is also taken to be a meaningful section designated as LAST + 1. Meshes may take a variety of interesting forms from simple pie-shaped sectors with no interiors (posts all at the same location), or a representation of the NORAD defense sectors, or even an inward spiral forming several layers in an ingenious state-like map. The information about barriers and meshes is converted and stored in vector component form for more rapid utilization by other programs.

With proper key indications ATLAS will write the constructed facility record on tape one (as the next logical record). One may also have ATLAS retrieve a previous written facility record from tape one with or without further card extensions. As many as a thousand facilities in up to thirty sets may be placed in one record.

STRIKE

The STRIKE program can perform a number of interesting tasks related to targeting. The principal task is to make a reasonably coordinated pre-war allocation of various portions of a mixed stockpile of offensive warheads against selected sets of targets under various restrictions that the attacker might wish to impose. The end result of this consideration is the creation of a warhead record. This is a listing for each of the warheads used of their generated aimpoints with provision for later insertion (by other programs) of origin of launch and probability of kill before reaching target. The record is segregated by warhead types and contains its own keying information so that it may be read later if stored.

Warheads may be grouped into different types because of actual differences in warhead characteristics such as yield, CEP, etc. or because the attacker would prefer to use them in different waves (times) or for different objectives or delivered by different carriers. Up to two thousand warheads split into as many as twelve different types may be considered in any one allocation and placed in the same record. The attack, or at least this portion of it, is described by specifying the total number of warheads of each type, the order in which the types are to be allocated (not necessarily the order of arrival), their expected probability of abort and CEP.

STRIKE presumes that there is an appropriate facility record in memory containing the sets desired to be targeted. The chosen sets are requested in any desired order and for each target set - warhead type combination the attacker's desired constraints are stated. The main restriction is the most number of warheads of this type that will be allowed to any one facility of the set. A blank or zero here means no interest in this combination and the program proceeds on to those combinations where positive allocations are permitted. Where and within the stated limit allocation is possible, two basic choices are open for determining the relative allocation amongst the contending targets - requirement targeting or value targeting.

If the requirement option is chosen, the attacker is permitted to specify the least number of warheads he would like allocated to any target of the set. If least is the same as most, the user has completely determined the allocation for this combination regardless of other factors except the stockpile size. If a tolerance exists between the least and most bounds, a third number - a required probability of kill for each facility in the set - resolves the allocation to within fractional warhead round off (which may also be controlled). The probability of kill level is however the weakest of the constraints and will not be held to when it lies outside the stated bounds.

When targeting by value options are permitted, these are considered only after the particular warhead type has fulfilled its requirement obligations. The remaining stockpile is then available for distribution by value. The object is to maximize the total value destroyed. The allocations of previous warhead types leave the target complex with a reduced set of (expected) values. Targets within the currently allowed sets compete with each other, whether of the same set or not, based both upon their remaining values and their respective softness to the current warhead type. Softness is computed for each potential target as the average single shot probability of damage, based upon a specified matrix of weapon radii for each warhead type - facility set combination, and previous specifications for warhead CEP, probability of abort, and target sizes. If desired for certain warhead types, the attacker's estimates of the relative penetrability of the defense to specific targets can be introduced as an additional modifier of the softness. The value returned then is the product of the target's remaining value and its softness. In maximizing the value returned for the stockpile available only integral distributions of warheads are permitted. The mathematics underlying the program for finding the allocation has been given elsewhere¹.

¹ Academy for Interscience Methodology, AIM 65-T-18, Targeting Program Revised, by N. H. Painter, December 1964, pp. 5-10.

Once the allocation of the warheads is completed the list of aimpoints is constructed. For targets small in area the aimpoints coincide with the target coordinates and are taken from the facility record. For each missile block the appropriate array is generated from the ATLAS parameters and the aimpoints spread out over the array in sequential fashion as far as the allocation allows. For large area targets aimpoint patterns for each warhead type are computed to "cover" the target as uniformly and multiply as the allocation permits.

For some purposes it may be desirable to preserve the warhead record as it now exists in the form of unaborted aimpoints. This may be done by using blanks for the final two STRIKE data cards and setting the keys so STRIKE will write the record on tape 3. An alternative would be to proceed and read in a new set of probability of aborts and CEP's, which may be the same or different from the previous estimated ones. In this case STRIKE will convert the aimpoints to impact points with the prescribed randomization and will initialize each warhead's probability of kill as starting out with the specified probability of abort. If desired STRIKE will immediately Monte Carlo this set of probabilities into random go-no-go choices. The warhead record in its completed form may then be preserved on tape. In either case whether the record is put on tape or not it remains in memory.

STRIKE might also be called in order to retrieve one or more warhead records from tape as needed thus obviating the need for reinputting and recomputing attacks which can be used multiple times. When this kind of call is made the option exists of either accepting the record as is or setting up a new abort and/or impact pattern. The latter would be a particularly convenient manner of performing Monte Carlo sensitivity analyses.

Finally one may call STRIKE again in the same run after a certain amount of damage assessment has been recorded on a facility list and request additional targeting be generated. The updated values of the targets selected will be used (whether the damage was of the direct or colocation nature) instead of the pre-war values. This presumes of course that the attacker has gained knowledge of this damage sufficiently well and in time to incorporate it in this targeting round. Since a new warhead record is hereby generated, the offense force structure involved may be more of the old force or contain new types or both. Thus as one progresses from one warhead record to the next, references to warheads of type one and two for example may retain their meaning while types three and four have changed.

MOTION

The MOTION program relates sets of facilities and warheads to one another in various ways. In doing so it makes extensive use of the barriers and meshes which have been set up by ATLAS. Most of the global geometric relationships are explored by means of the MOTION program. Besides generating information for its intrinsic value certain specific information may be useful in DEFEND, particularly for area defense systems. Four distinct functions are currently included within the program, each explained in the following paragraphs. None are restricted by frequency or order of utilization.

By selecting a particular mesh and naming other facility sets, the sites within each named facility are located according to the sector containing their latitude and longitude. A count of the sector distribution of sites is made and printed along with a listing of the sector number for each site. The sector designation for the site in the facility record is hereby tagged with the latest determination. Facilities which are not found in the facility record currently in memory are ignored. If the mesh is not in record, return is made to BEAM.

By selecting a particular mesh and naming certain facilities which are suitable for launch sites for selected warhead types, each warhead in the sets chosen will be tagged in the warhead record with an

appropriate launch site. The method for determining the launch site starts by locating the sector number of the named mesh that contains the aimpoint or impact point of the warhead. The sector number is then used to find a corresponding site in the launch set. If, for example, a warhead fell in the third sector, the third launch site of the specified set would be presumed to be the desired and appropriate site. There should be at least as many sites in the launch sets as there are sectors; however, a given site may be listed more than once, and a given set may be used for more than one warhead type. This method is particularly attractive when range is not the dominant routing criterion and the user wishes to do his own broad brush positioning of launch or penetration points. If the warheads are to be defended against by sector oriented defenses, this should be the method for sector tagging the warheads using the same mesh as the defense. Otherwise, the mesh need not correspond and could be specially designed for the routing topology.

Without using a mesh but naming launch facilities for other warhead types together with maximum range constraints for each type, a different kind of selection of launch sites will be made. In this method the launch site which is closest to the impact point from among the designated facilities is found by computing the great circle distances. If the range is within the allowed max this association is accepted. If not, the particular warhead is given an artificial "out-of-range" kill and will

not be seen by later defenses or cause any damage assessment. The out-of-range feature can under certain circumstances be a planned phenomenon for achieving a modified targeting plan. Short range weapons used for hold down or defense roll up might well be targeted this way. Counts of the out-of-range kills as well as the loads placed upon the penetration or launch points in order to meet the in range targets are printed out.

By naming appropriate barriers for selected warhead types, for whom launch sites have been previously designated, information relative to the attack crossing these barriers can be obtained. For each warhead the position where the great circle arc from launch to target crosses the selected barrier is found. Not every warhead may cross. For some the target may lie outside the barrier, i.e. Honolulu, while others may be launched interior to the barrier. Other paths may cross more than once in which case the first computed crossing (lowest numbered arc) is used. For each arc of the barrier the sum of the probabilities of survival of the penetrators crossing that arc (surviving penetrators if Monte Carlo has been made) is printed out as well as the weighted average of time to go from arc to target. This information is not however currently retained in memory.

DEFEND

The DEFEND program is called for the single minded purpose of increasing the attrition on the attack. The program may be called at various times and in each call selected sets of defense facilities may be requested to do battle in arbitrary order or repetition. A variety of local area, missile, and aircraft defenses may be included. In each defense battle the defense facility is faced with the presence of a possibly mixed selection of offense types in a common time span.

Several geographical mechanisms are available for confining the general commitment of each defense site or sector. Within the confined environment the efficacy of the site's normal attrition capability becomes limited with increased rapidity of events as the total raid is compressed in time. The actual locale of the battles are not sought nor are detailed intercept assignments or geometry computed. Given reasonable computation of forces which the defense can mount and the segments of the offense they are directed at it is not unreasonable to manage the intercept variations as a random application of kill potential to moving targets.

Each defense site listed in the atlas facility takes its turn at doing battle in order. The simplest commitment mechanism is that appropriate to local terminal defenses. The sites have a circular radius of coverage around their physical coordinates. This coverage may vary

with penetrator types including shrinking to nothing at all. Those warheads which are scheduled to impact within the coverage and which are still alive at the time the site is ready to commit constitute its threat. Note the coordination which is thereby achieved by overlapping sites since a first site kill will not be a second site target but a first site failure will.

A second commitment mechanism is more appropriate to area missile defense as such sites are not likely to be deployed near targets they defend. In this an effective circular intercept coverage around the sites are assumed as before but this time at some altitude. The footprint or ground projection of the equivalent coverage depends upon the direction and angle of reentry of the missile attack. With such information for the various missile types the down range displacements are inserted. A similar type coordination occurs when footprints overlap.

Either of these geometrical partitioning may of course be applied to aircraft defenses, particularly of the Hercules or Bomarc type. For long range fighters the facility "sites" might be taken as centers of NORAD sectors of responsibility or air cap positions displaced up range to the center of battle coverage, although the "reentry" is awkward in the latter case. A third procedure is to request defense by sector. This entails that a mesh appropriate to the sectorizing be included in ATLAS, the defense facilities located by sector by MOTION, and the defendable penetrators sector tagged by MOTION with the same mesh. Each site

then battles those penetrators with the corresponding sector designation. A fourth procedure is to use a simultaneous constraint of radius of coverage and sector coincidence, but an application is not apparent.

Whatever the commitment partitioning procedure is, an actual count of surviving penetrators is made. For the defense environment point of view this count is modified. If, for the span of time allocated to this raid, a group of penetrators can be presumed to be all in the battle area and remain there throughout each then has the same dwell time as the raid time. If a second group of fast moving penetrators all pass through the battle area during the raid interval it is assumed that they enter and leave at random times. Each has a dwell time that is only a fraction of the raid time and the number present at any moment will be on the average this same fraction. A third group of penetrators may enter and leave the battle area at random moments, not because of their speed, but because their entries are straggled out over a long time relative to the raid interval. Their dwell time should also be shortened to reflect the lower density present during the raid. However, when handled this way the defense only receives justice if repeated raids are called on the stragglers. Generally little is lost computationally by time collapsing a straggled raid into one separate simultaneous raid if saturation and inventory ready allowances are made.

The count of penetrators present may be further reduced by a visibility factor or increased by the portion of the cloud of false bogies

accompanying the visible penetrators which cannot be successfully discriminated against by the particular defense. This total density of bogies persist throughout the raid time although for fast penetrators the identities may be changing. The number of tracks a site or sector is able to maintain generally has an upper limit so that the probability a given bogie is a track decreases as the number of bogies approach the saturation limit. This probability of track is taken of the form

$$PT = e^{-\frac{1}{2} \left(\frac{\text{BOGIES}}{\text{SATURATION}} \right)^2}$$

If the bogies greatly exceed the limit the number of actual tracks may in fact decrease. Each intercept made on a track requires a ground data link or communication channel, an interceptor salvo and a certain amount of time. The total number of intercepts made during the raid may be limited by channel duty rates, interceptor ready inventories or failing either of these a command limitation when a satisfactory number of intercepts per distinct bogie is attained. (If the average dwell time is half the raid time, the number of distinct bogies will be twice the number that are on the average present.) The interceptor inventory may or may not be required to be counted down as intercepts are made. There are rational applications for both missile and fighter type defenses for either request. The number of intercepts per track per unit time is computed.

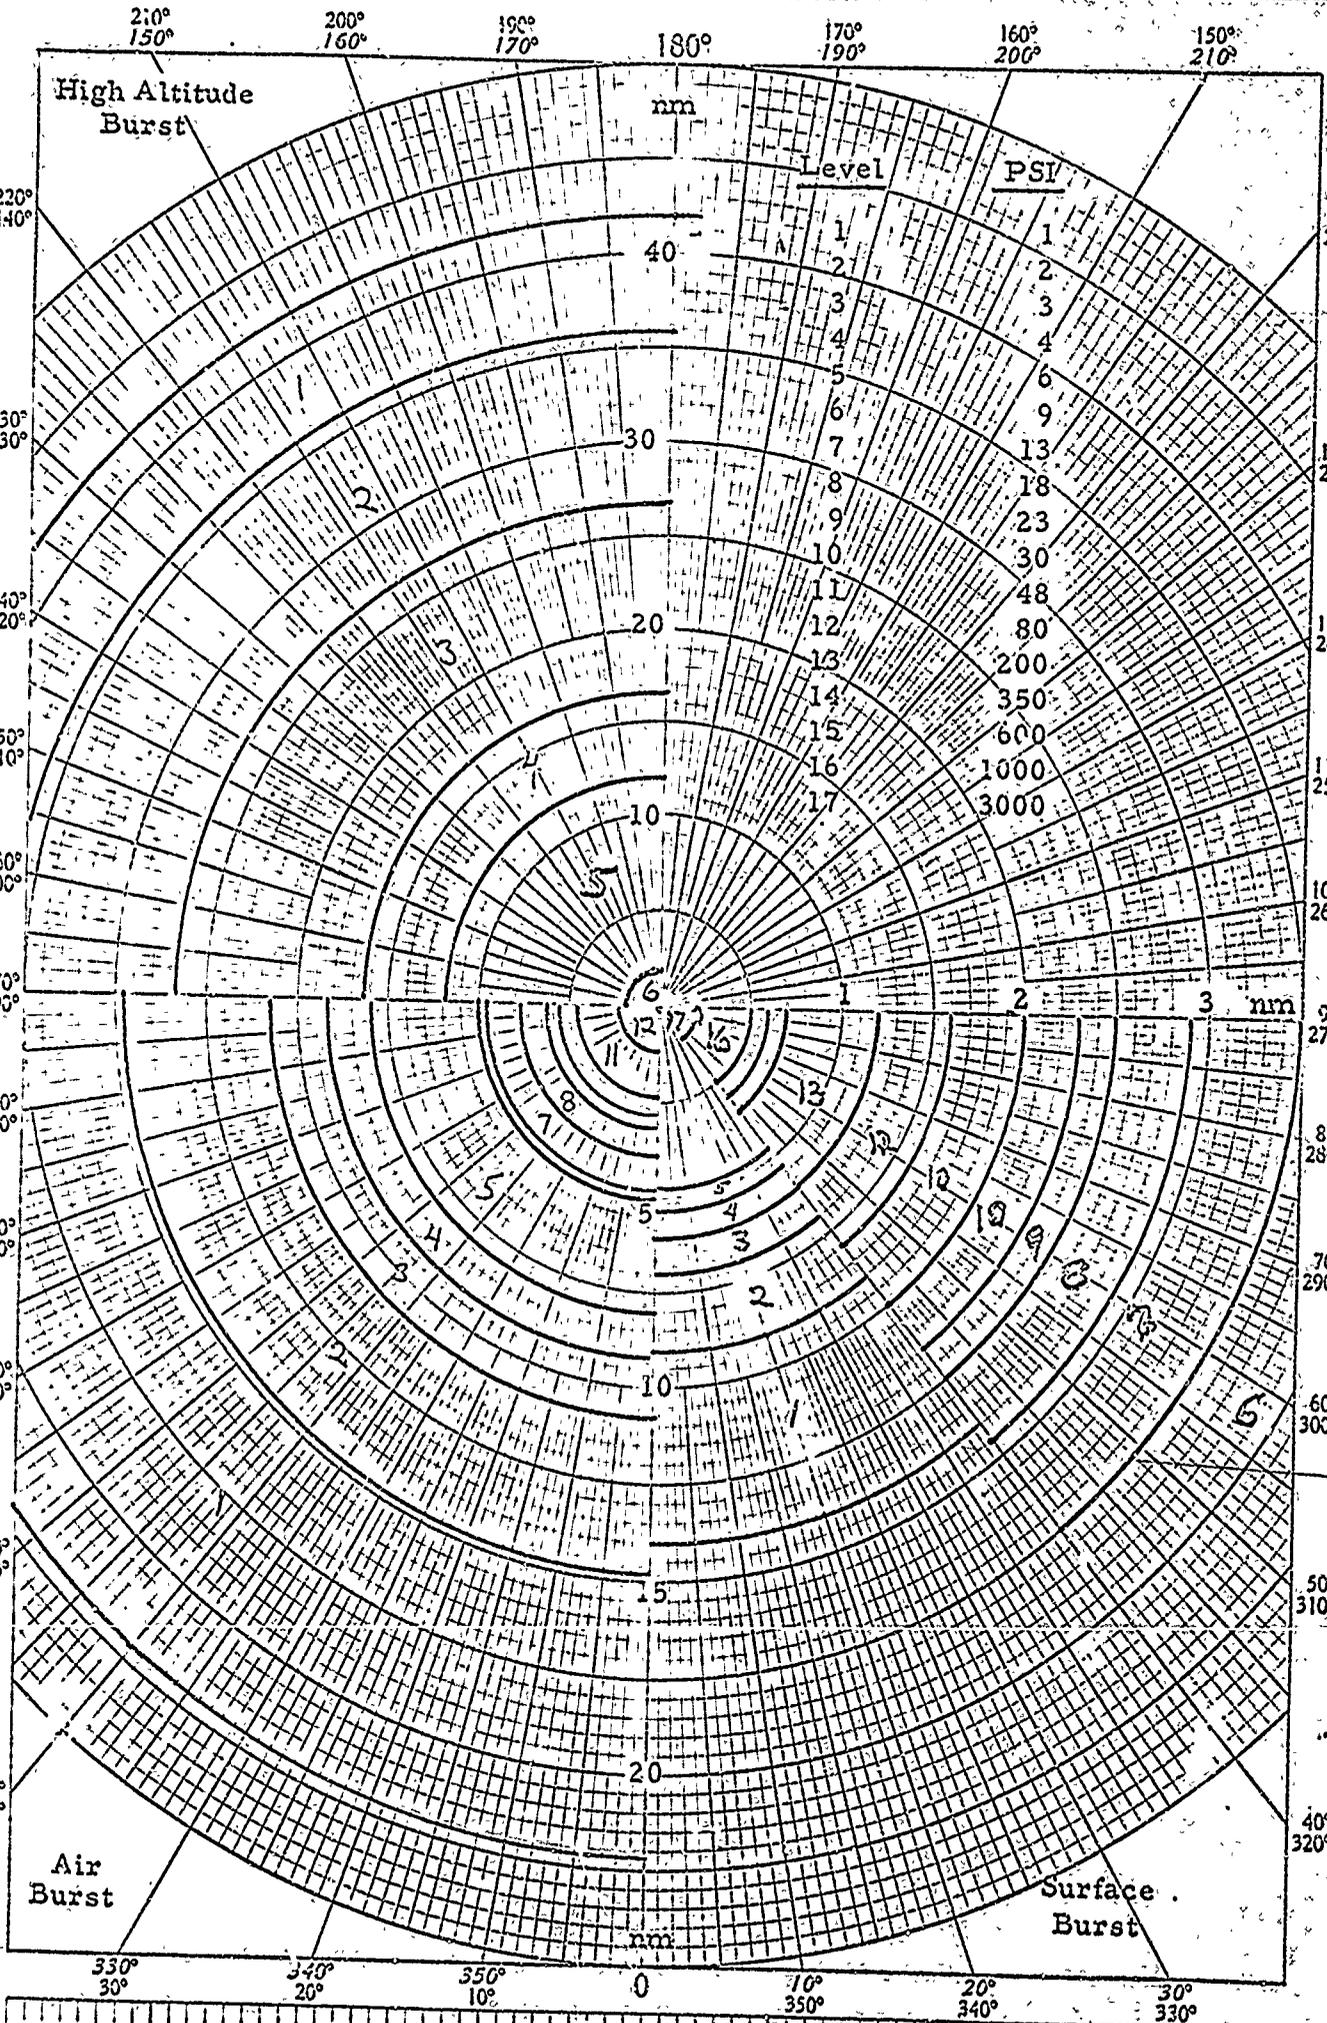

The probability of survival of every warhead within the coverage decreases in relation to the probability of kill of the penetrator type per intercept, the number of intercepts per dwell time, and the probability of being tracked.

If desired the expected probabilities of kill may be left to accumulate through several battles or they may be Monte Carloed each time. It is generally desirable to have each warhead Monte Carloed at least the last time before entering the damage assessment program. The expected number of defense kills and opportunities for each site and penetrator type is printed out for each battle.

ASSESS

The ASSESS program manages all the damage assessments desired on any or all real facilities whenever warheads have passed through the defense. Facilities do not have to have been targets and colocation damage is accounted for. When it is called into memory by the BEAM monitor, the next four input cards are read. These cards establish the desired yields (in megatons), the thermal efficiency adjustments (normally unity), the fission-fusion fractions, and the altitude type of burst (surface, air or high altitude) for all of the various warhead types. The program contains numerical data which define blast contours, thermal contours, and fallout contours. This basic data is for a 10 MT warhead with 50-50 fission-fusion. For blast these contours are concentric rings of lbs per square inch overpressure at various nautical mile distances from ground zero (Figure 1). For thermal they are rings of incident calories per square cm at various nautical mile distances (Figure 2). For fallout the contours are a nested set of oblong rectangles skewed toward the down-wind (easterly) direction, for total roentgens received in 48 hours with no protection (Figure 3). The blast and thermal contours change for each of the three different altitude type bursts, while the early fallout is assumed to be appreciable only for surface bursts. For a particular warhead

type the appropriate altitude contours are scaled to the correct yield; for blast and fallout the scaling is by yield to the 1/3 power, for thermal by yield to the .42 power.

A particular set of warheads are withheld from consideration during the current assessment if their altitude types are set to a negative one. This permits different offensive components of the same strike to be assessed by different assessment calls. One advantage of this procedure occurs when the strike contains some time delayed elements and the defense survival and effectiveness can be studied and altered between waves. An alternate procedure which is some times useful is to construct one "strike kit" such that different combinations of warhead types represent different threat levels or targeting objectives. Each assessment then represent the effectiveness of one of the threats. In one application, the low threat was obtained by taking only warhead types 1 - 5, the medium threat was obtained by augmenting the low threat with those warheads called type 6, and the high threat by the further augmentation of warhead type 7. Warheads of type 5, 6, and 7 were all physically alike, the distinction being only in the extent of targets hit.

When the warhead initializations are complete, requests to assess damage to classes of facilities are processed. Each subsequent input card requests one class in the facility atlas be assessed and

supplies the levels of blast, thermal, and fallout stress (or protection) considered to be acceptable for that class. On the basis of the class name supplied (and previous ATLAS information) the subroutine distinguishes the need for five different procedures, depending on whether the class represents 1) bases or sites with similarity in area and function, 2) strategic missile squadrons or "blocks", 4) urban areas with shelter data (on tape prepared by the SHELL subroutine), or 5) "rural population" or continental map of values. Most military installations, with the exception of missile blocks, are usually considered to be treatable by the first procedure, and this is the one discussed in detail. The area of the base (πR^2) times the density of evaluation points per square nautical mile (both inputs) determine how many evaluation points are to be placed around each base. This number is at least one but no more than 400. Whatever the number, a squarish pattern of that many points is constructed, centered on each base and scaled to cover the equivalent area of the base (Figure 4).

For each base in the facility class, the list of warhead impact points is examined. Warheads which have aborted, or been successfully defended against, or disallowed (by the altitude ban mentioned above) are skipped. Those impacts which are too remote to affect the particular bases are also skipped. For each remaining

warhead the appropriate effects contours are placed around the impact point. The location of each of the base evaluation points is found with respect to the three sets of contours and the respective PSI, calorie, and roentgen doses that would be received from each detonation at the evaluation point are weighed. For blast and thermal doses the point is charged with receiving the maximum levels found among all the warheads detonating while for fallout the dose is the cumulative of each warhead's contribution. In order to present to the analyst an indication of the effects experienced on each facility of this type, the three types of dosages are averaged over all the target's evaluation points and these averages are pointed for blast, thermal and fallout before target vulnerability to the "absorbed" effects are considered.

When the doses have been computed for all the evaluation points around the base, the base survival is considered. The probability a particular evaluation point, considered to represent a portion of the base, survives is determined from functions of the effective doses received, which are the actual doses relative to the (input) stress limits for the facility class. For blast and thermal the functional relation is e^{-x^2} (Figure 5), while for radiation it follows a fatality table (Figure 6). The fraction of the base as a whole which is killed by blast is the number of evaluation points which do not survive the

the blast alone. The fraction of the base killed by thermal is the count of points which survived the blast wave but did not survive the fire or thermal effects. The portion of kill attributed to radiation would be those which escaped the first two effects yet received a fatal roentgen dose in spite of the protection factor. To find what effectiveness fallout alone would have an assessment call could be made where the other effects are "turned off". The value of the base is assumed to be uniformly distributed over its area or equivalently its points and the value surviving that is printed out is that portion which survives all three effects. If, as sometimes occur, multiple independent assessments are desired, the option of leaving the base value in memory unchanged may be specified. Normally, the value decreases with successive assessments. The total values surviving or killed by each of the effects is summed and printed out for each facility class at the end of its processing. A blank card ends each assessment call and returns control to the BEAM monitor.

The rural population does not occur as a facility in ATLAS. It or any other regular geographical array of values, such as rural MVA, may be assessed by directly reading in a density "map". Each 1° by 1° latitude-longitude square corresponds to a base or urban area in the normal procedure and has its own value. A specified square density of evaluation points are arranged symmetrically to cover

every cell (max 10 by 10) and the nation has a regular pattern of evaluation points except for the adjustment which is made for the cosine of the latitude. The value of a cell is represented as an alphanumeric character on a scale 0-50 with an arbitrary scale factor for the map as a whole. Each input card gives the latitude string of characters for a given latitude band, and the set of cards are in latitude order north to south. Blank cells are not assessed. The output is represented in the same format as the input with maps for the survivors, blast kill, and fallout kill distribution. Cumulative nationwide totals are also printed out.

SHELL

This program is concerned with providing data on the blast and fallout protection the population might have in various circumstances. The output can be made available to ASSESS which enables the latter to perform a more sophisticated evaluation than it would otherwise. Three distinct functions can be performed using SHELL.

A basic set of data is required to describe the physical number and nature of the shelter spaces that exist at each facility site. The natural facility is of course the urban areas and this is the one for which a data bank has been accumulated and used. There is no reason why similar data could not be applied to military or other facilities that contain special groups of people. The national shelter survey was the source for creating the urban shell deck. Since the origin form of the data was not accumulated in a manner to be applicable to urban areas, selected component data was punched on cards for various parts of the urban complex. This consists of the number of spaces in the standard PF and PV categories defined by OCD. The first function and use of SHELL is to tabulate and order the totals to match the site list in the facility record, in this case

the 213 U.S. urban areas arranged by rank (identical to the 1966 Census Bureau ranking). This is one instance where order in the facility record is important. The tabulation is usually made once since survey data generally do not change often and a permanent shell tape written. Thereafter, the master tape is used to generate the operating tapes for SHELL and ASSESS. Both assume that the urban deck matches in number and order of places.

The second function that SHELL may do is to construct and add additional shelter spaces as directed. The new spaces may be constructed at a specified PF or PV category or both. The number added to any given place will depend on if and how much deficient that place falls below a requested criterion. The implication in terms of the national total spaces constructed is printed out.

The third function is to distribute at each place its population value in some manner into the various shelter spaces it has available. One choice, which might be suitable when long strategic warning occurs, would be to take maximum protection. In this case the hardest spaces are filled until either there are no more people or no more spaces. An opposite or no warning case would leave a percentage of the population with minimum protection. The remainder fill up the spaces in a pessimistic fashion, first next poorest and on

up perhaps leaving the best spaces empty. The most realistic option assumes that all shelters regardless of type are filled to a certain percentage of capacity, the percentage utilization specified. Any remaining population has minimum protection.

Any number or mixture of utilization can be stacked on a temporary or permanent tape for concurrent or later ASSESS requests.

SURVEY

The SURVEY program has been brought under the operating command of the BEACON monitor and is exercisable. It is currently more autonomous and thereby less in the battle stream than the other programs. When the Task 41 study settles upon an MCI attrition model, it potentially may relate strongly to SURVEY and together integrate more firmly. At present SURVEY may be used to explore questions concerning missile and satellite trajectories, their visibility by one or a group of sensors, and potential warning or intercept aspects.

A number of objects may be launched from arbitrary places and directions around the globe with simple or elaborate descriptions of the boost stages and thrust forces. The gravitation attraction forces by the oblate earth are accounted for and the drag forces change with altitude and cross section in a density-temperature varying atmosphere. The spatial and rotating earth trajectories are integrated from the force equations. A trade-off between speed (of computation) and accuracy may be made.

A group of sensors may be deployed any where. These sensors which contain the trajectory in their horizon are indicated as a function of time as well as the object position in sensor coordinates.

COMAND

The COMAND program is a utility aid in providing visual plots of various geographical relationships between either sets in the facility records or in the warhead records or both simultaneously.

A separate map is produced with each call. With a 1° cell resolution the map frame can be as large as 50° in latitude by 120° in longitude. Larger or smaller areas of the globe may be framed with a corresponding loss or gain in resolution. The frame may be positioned anywhere. The U.S. may be nicely framed by a $25^\circ \times 60^\circ$ map with $1/2^\circ$ cell sizes.

By naming a record, facility or warhead list, a facility set or type, and supplying a symbol, the program will print that symbol in every cell containing such a site or impact. Several requests may be made for the same map when one wishes to view the correlation between them. Clutter however should be avoided as multiple entries to the same cell result in converting the symbols to asterisks.

UTILIZATION OF THE PROGRAMS

The BEACON Monitor is initially given program control. The first card of the data deck is a date card which supplies the date, a name or number, and eight words for identification of the run. This information is printed out at the very beginning as part of the heading for the run. The monitor is able to read cards in any format; it passes them by until it comes to a BEAM card, which is identified by the word "BEAM*" in the first six columns of the card (the quote sign " signifying a blank character). The next word (col 7-12) is a subroutine name and must be spelled precisely as one of the available routines ATLAS", STRIKE, DEFEND, ASSESS, SHELL", MOTION, SURVEY, COMAND or be completely blank. Any other combination of characters, such as END, acts as an end of run signal to the monitor. After the monitor has processed the remaining information on the BEAM card, control is then passed to the appropriate routine requested. As each routine completes the work for which it was called, control is returned to the monitor which resumes scanning the data deck for more BEAM* cards. It is in this manner that the user achieves his participation in the battle. By dividing the problem into appropriate segments, arranging their order and inserting BEAM* cards as definition of this control, the user literally commands the computer to perform the detailed calculations for a battle which he outlines.

Examples of some hypothetical deck set ups may be helpful. Simple preliminary jobs are given first.

- 1) Form a raw shelter tape for permanent use from the survey data, no construction, no utilization.

Date card

BEAM* SHELL"

keys { 2=2

SIBFTC RND3DK DECK
FUNCTION RANDOM(X)
COMMON /PAR/ DAT(4),RANDA,RANDB
DO 12 J = 1,2
  RANDB = RANDB + RANDA
  RANDA = RANDB - RANDA
IF (RANDB .GE. 1.0) RANDB = RANDB - 1.0
12 CONTINUE
RANDOM = RANDA
RETURN
END

```

The purpose of the function RANDOM(X) is to generate a new random number from a uniform distribution on the interval 0 to 1. The procedure used is a Fabonachi type in which the last two numbers generated, RANDA and RANDB, are remembered and used to form the next one. Two non-commensurated numbers are supplied from the compiled parameter list to start the process.

SIBFTC PKA2DK DECK

FUNCTION PKAY(AT,AW,SZ)

COMMON /PAR/ DAT(14),CPK1,CPK2,CPK3

DIMENSION NC(50)

DATA(NC(J),J=1,50)/12*61.55,43,37.2*31,4*19.2*13.11*7.8*4.5*3.3*27.18

PKAY = 1. - PS**((1./ANC)

RETURN

END

The purpose of this function PKAY(AT,AW,SZ) is to compute an estimate of the average fraction of remaining value destroyed by each weapon of lethal area AW and variance SZ that may be aimed at a target of area AT. The shape factors, CPK1,2,3 are normally set so that for targets of area less than the weapon (aimpoints all at center of target) the function reduces to the usual single shot probability. Targets of large area and unusual shape might be approximated by other shape factors.

```

SIBFYC DISIDK DECK

20 LOCATE = J - KB + 1
RETURN
END

```

The function LOCATE(Y, X, K) determines in which section of a mesh a particular point lies. The arguments are the latitude and longitude of the point and the facility type number K of the desired mesh (usually preselected by the calling program). The procedure tests all sectors in order from one to last until a positive association is determined. If no association is found, the point is automatically classified as last + one. A point is in a sector when it lies to the right of the left hand heading looking outward, on or to the left of the right hand heading, and on or exterior of the sector arc. Exterior means to the left as the sector posts are traversed in increasing order.

```

The function VIND(X, XD) with alternate entry point

DPNV(X, XL) is a general purpose routine to integrate up to fifty simultaneous first order differential equations. It is used by SURVEY to integrate the three second order (equivalently six first order) differential equations governing a missile or satellite orbit. While using only single precision instructions and arguments, it achieves double precision accuracy by itself saving, then retrieving next call the second word worth of digits for each variable. A call to VIND is used to increase the independent variable where X is the current time and XD the increment; a call to DPNV is made for each dependent

variable to be integrated where X , \dot{X} are the current values and first derivative respectively.

This program was originally obtained as a binary deck in 704 machine language from Lincoln Laboratories for use with Fortran II programs. It was rewritten by the author in MAP language to be compatible with the Fortran IV computer. It is this form or its corresponding binary deck which matches the SURVEY program included in this report. However MAP programs are not easy to understand. Since the MAP version has been rewritten in Fortran IV under another contract (to make it useable on a CDC 3600 machine) this more readable version is used here. It has been tested on the 7094 with SURVEY. (A few card modifications are required in the latter.)

SUBROUTINES

SIBFTC RAN1DK DECK

SUBROUTINE RANORM(X,Y)

A = 6.2831853 * RANDOM(X)

R = SQRT(-2.0 * ALOG(RANDOM(Y)))

X = R * COS(A)

Y = R * SIN(A)

RETURN

END

The routine RANORM(X Y) computes two random rectangular displacements based upon a circular normal distribution with mean zero and standard deviation unity. The procedure is to combine a random radius, computed as the inverse transformation of a uniformly sampled probability supplied by the RANDOM function, with a uniformly sampled angle from 0 to 2π . The results usually need to be scaled to the proper deviation and centered on the aimpoint to form an impact point.

The COORD(MW,K) subroutine is used to find aimpoints for the warheads of each type assigned by STRIKE to any targets (except missile blocks which are deployed differently by STRIKE itself). The target coordinates, radius, and warhead radius is passed to COORD indirectly by STRIKE having stored them in the common block /MON/. Depending upon the relative size of the target to warhead radii aimpoints are chosen either at the target coordinates or in a patterned array around them. The array will also be influenced by the number of weapons MW to be put down and may if MW is large enough give

multiple coverage. Normally the patterns are not scaled but they may be expanded or contracted by changing the parameter DILATE. The impact coordinates are stored, segregated by warhead type, by means of the index argument K.

```

It is sometimes desirable to substitute a "DUMMY" subroutine in place of one or more of the main routines in runs where it is known that such routines will not be exercised. This is particularly true when submitting the program in card form, either source or binary decks as considerable weight and space may be saved. This program is a simple DUMMY which has been so used in this instance to replace the SURVEY routine.

13. ABSTRACT		
<p>BEACON denotes a set of programs organized to form a computing tool to study defense of the continental United States against strategic nuclear attack. The purpose is to obtain a feel for the possibilities of newer technological concepts useable in continental defense. Thus, BEACON has been designed toward embracing any set of potentially interesting interacting systems of the near future. The method of procedure has been to concentrate on fundamental logical or physical processes of attack and defense on a global scale and to keep the structure modular, replaceable, and open-ended.</p>

INSTRUCTIONS

1. **ORIGINATING ACTIVITY.** Enter the name and address of the contractor, subcontractor, grantee, Department of Defense activity or other organization (*corporate author*) issuing the report.

2a. **REPORT SECURITY CLASSIFICATION:** Enter the overall security classification of the report. Indicate whether "Restricted Data" is included. Marking is to be in accordance with appropriate security regulations.

2b. **GROUP:** Automatic downgrading is specified in DoD Directive 5200.10 and Armed Forces Industrial Manual. Enter the group number. Also, when applicable, show that optional markings have been used for Group 3 and Group 4 as authorized.

3. **REPORT TITLE:** Enter the complete report title in all capital letters. Titles in all cases should be unclassified. If a meaningful title cannot be selected without classification, show title classification in all capitals in parenthesis immediately following the title.

4. **DESCRIPTIVE NOTES:** If appropriate, enter the type of report, e.g., interim, progress, summary, annual, or final. Give the inclusive dates when a specific reporting period is covered.

5. **AUTHOR(S):** Enter the name(s) of author(s) as shown on or in the report. Enter last name, first name, middle initial. If military, show rank and branch of service. The name of the principal author is an absolute minimum requirement.

6. **REPORT DATE:** Enter the date of the report as day, month, year; or month, year. If more than one date appears on the report, use date of publication.

7a. **TOTAL NUMBER OF PAGES:** The total page count should follow normal pagination procedures, i.e., enter the number of pages containing information.

7b. **NUMBER OF REFERENCES:** Enter the total number of references cited in the report.

8a. **CONTRACT OR GRANT NUMBER:** If appropriate, enter the applicable number of the contract or grant under which the report was written.

8b, 8c, & 8d. **PROJECT NUMBER:** Enter the appropriate military department identification, such as project number, subproject number, system numbers, task number, etc.

9a. **ORIGINATOR'S REPORT NUMBER(S):** Enter the official report number by which the document will be classified and controlled by the originating activity. This number must be unique to this report.

9b. **OTHER REPORT NUMBER(S):** If the report has been assigned any other report numbers (either by the originator or by the sponsor), also enter this number(s).

10. **AVAILABILITY/LIMITATION NOTICES:** Enter any limitations on further dissemination of the report, other than those imposed by security classification, using standard statements such as:

- (1) "Qualified requesters may obtain copies of this report from DDC."
- (2) "Foreign announcement and dissemination of this report by DDC is not authorized."
- (3) "U. S. Government agencies may obtain copies of this report directly from DDC. Other qualified DDC users shall request through _____."
- (4) "U. S. military agencies may obtain copies of this report directly from DDC. Other qualified users shall request through _____."
- (5) "All distribution of this report is controlled. Qualified DDC users shall request through _____."

If the report has been furnished to the Office of Technical Services, Department of Commerce, for sale to the public, indicate this fact and enter the price, if known.

11. **SUPPLEMENTARY NOTES:** Use for additional explanatory notes.

12. **SPONSORING MILITARY ACTIVITY:** Enter the name of the departmental project office or laboratory sponsoring (*paying for*) the research and development. Include address.

13. **ABSTRACT:** Enter an abstract giving a brief and factual summary of the document indicative of the report, even though it may also appear elsewhere in the body of the technical report. If additional space is required, a continuation sheet shall be attached.

It is highly desirable that the abstract of classified reports be unclassified. Each paragraph of the abstract shall end with an indication of the military security classification of the information in the paragraph, represented as (TS), (S), (C), or (U).

There is no limitation on the length of the abstract. However, the suggested length is from 150 to 225 words.

14. **KEY WORDS:** Key words are technically meaningful terms or short phrases that characterize a report and may be used as index entries for cataloging the report. Key words must be selected so that no security classification is required. Identifiers, such as equipment model designation, trade name, military project code name, geographic location, may be used as key words but will be followed by an indication of technical context. The assignment of links, rules, and weights is optional.
